## Abstract

For the optimal function of thyroid gland, adequate intakes of iodine and selenium are required. Since iodine is essential component of the thyroid hormones, its insufficiency leads to inadequate hormone production and further to inadequate tissue response (hypothyroidism), goitre, stillbirth and miscarriages, and growth retardation. According to the World Health Organisation the recommended median urinary iodine concentrations (UIC) are the best indicators of iodine nutrition. The WHO defines iodine sufficiency in an adult population as a median UIC of  $> 100 \mu\text{g/L}$  in spot urine samples. Iodine deficiency was and still is a problem in New Zealand. In September 2009 the mandatory fortification of all bread with iodized salt was introduced. Therefore, the primary aim of the study was to determine the levels of iodine in both groups, and the secondary aim of the study was to determine whether there is a relationship between selenium and iodine, and iodine and thyroid hormones in two groups of European women. Urinary iodine concentration was determined in spot samples by the new method called "Fast B", which is improved Sandell-Kolthoff reaction. The results of the study showed the mean urinary iodine level in the control group and the group of women with the Hashimoto's thyroiditis was  $120.77 \pm 59.35$  (median UIC was  $128.00 \mu\text{g/L}$ ), and  $98.64 \pm 62.83$  (median UIC was  $95.00 \mu\text{g/L}$ ), respectively. Estimated daily iodine intake of  $150 \mu\text{g/day}$  was achieved in five participants in the control group, and four participants in the group of women with Hashimoto's thyroiditis. Estimated median iodine intake in the control group and Hashimoto's group was 142.22 and 105.55, respectively, indicating mild iodine deficiency. There was no significant relationships found between iodine and selenium, and iodine and thyroid hormones in both groups. The results of the current study are in line with the results from larger studies carried out in New Zealand. Iodine intakes appear to have improved after the mandatory fortification of bread with iodised salt in 2009, although iodine deficiency is still a problem in New Zealand. Using an iodine fortified bread clearly made an impact on the overall iodine intake but not to the expected level. There was no association found between iodine and selenium, and iodine and thyroid hormones. Any possible interaction between selenium and iodine is still unclear.

## Introduction

The synthesis of the major thyroid gland hormone thyroxine occurs along the hypothalamic-pituitary-thyroid axis (HPT axis). HPT axis represents a complex series of pathways and feedback mechanisms [1, 2]. Adequate function of the HPT axis is critically dependent on the essential trace elements iodine, selenium and iron, although most closely associated are iodine and selenium [3]. The thyroid gland contains the highest iodine and selenium concentration among the human tissues and organs in the human body. For the optimal function of thyroid gland, adequate intakes of iodine and selenium are required [4]. Inadequate iodine intake can cause deficiency which might impair the synthesis of thyroid hormones, tetra iodothyronine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>), whereas selenium is essential for the synthesis of selenoenzymes whose deficiency is implicated in disorders of thyroid hormone metabolism, and thyroid gland function.

The crucial step in thyroid hormone synthesis is the direct binding of TSH to the TSH receptors (TSH-R). [5]. Iodine is taken by thyrocytes from blood plasma through the actions of the integral plasma membrane glycoprotein sodium/iodide symporter (NIS), which mediates the active transport of iodine into the thyroid follicular cells [6]. The next step in thyroid hormone synthesis is the process of thyroglobulin (Tg) iodination, which occurs inside the lumen of thyroid follicles [7,8]. Thyroglobulin iodination requires iodide catalyzed by selenoenzyme thyroid peroxidase (TPO), and higher H<sub>2</sub>O<sub>2</sub>

concentrations generated in the apex of the thyrocytes, where selenium exerts one of its vital roles in peroxide degradation, cellular redox and transcription regulation, and thyroid hormone deiodination [3]. Overall, selenium plays a crucial role in the maintenance of metabolic, immune-endocrine, and cellular homeostasis, owing to its antioxidant and anti-inflammatory properties [9,10]. Selenium is an integral part of the iodothyronine deiodinases (selenoenzymes), that link selenium and iodide in a potentially important interrelationship in which one trace element might influence the metabolism of another [11]. Synthesized entirely by the thyroid gland, T<sub>4</sub> acts as a prohormone to generate T<sub>3</sub>. The process of peripheral mono deiodination of T<sub>4</sub> provides for the remaining 80% of T<sub>3</sub> daily production in healthy people, whereas thyroid gland itself generates 20% of the T<sub>3</sub> [12]. Biologically active T<sub>3</sub> is essential for normal development, growth, neural differentiation, and cellular metabolism [13].

Iodine is an essential component of the thyroid hormones, T<sub>4</sub> and T<sub>3</sub>, and makes 65% and 59% of their molecular weight respectively [14]. For adequate hormone supply, the thyroid gland has developed

an elaborate mechanism for concentrating iodine from the circulation and converting it to T<sub>4</sub>, which is then stored and released on demand. However, iodine insufficiency leads to inadequate hormone production and further to inadequate tissue response (hypothyroidism), goitre, stillbirth and miscarriages, growth retardation [15]. The most devastating toll is of the neurological and mental disorders resulting from the brain damage. In order to prevent iodine deficiency, the International Council for Control of Iodine Deficiency Disorders, the World Health Organisation, UNICEF, and the Food and Nutrition Board of the U.S. National Academy of Sciences, recommended dietary iodine intake (RDI) of about 150µg/day for adults being essential for the thyroid hormone synthesis [16].

Similarly, in Australia and New Zealand, the Estimated Average Requirement (EAR) and Recommended Dietary Intake (RDI) for adult women for iodine are 100 and 150µg/day. According to the World Health Organisation (WHO) and other international groups, the recommended median urinary iodine concentrations (UIC) are the best indicators of iodine nutrition [17]. The WHO defines iodine sufficiency (ID) in an adult population as a median UIC of > 100 µg/L in spot urine samples, providing no more than 20% of samples are >50 µg/L. The ranges where medians fall are far more important than the number. The ranges are arranged beginning with the severe iodine deficiency (0-19µg/L), moderate deficiency (20-49 µg/L), mild deficiency (50-99 µg/L), optimal iodine nutrition (100-199 µg/L), and more than adequate iodine intake of (200-299 µg/L), and excessive iodine intake ( $\geq$  300 µg/L) [18-20].

The signs and symptoms of ID in New Zealand were notified in the late 1800s and early 1900s and were characterized by endemic goiter and low UIC of less than 50µg/L. The major contributing factors for ID were low iodine concentrations of New Zealand soil and the reduction in the use of iodophors by the dairy industry [21]. In the early 1900s in order to decrease the incidence of endemic goiter in many parts of New Zealand, iodisation of table and cooking salt was introduced in 1924 at the level of < 40 mg/kg, although it was increased in 1939 to 40-80 mg/kg [22]. Following this increase in iodisation of salt, the incidence of goiter has dropped from 61% to 1.1% in the 1950s. For more than two decades iodine intake was adequate or more than adequate, owing to iodised table salt use and use of iodophors as equipment sanitizers in the dairy industry [23,24]. In the early 1990s, the use of iodophors decreased, and recommendations to reduce salt intake raised concerns that iodine intake might decrease. The study by Thomson *et al.* found that urine iodine concentrations were considerably lower than those previously reported [25]. However, iodine deficiency was and still is a problem in New Zealand and parts of Australia [26,27]. In September 2009 to prevent iodine deficiency, the mandatory fortification of all bread with iodized salt was introduced in both countries.

The primary aim of the study was to determine the levels of iodine in both groups and compare them with gold standards. The secondary aim of the study was to determine whether there is a relationship between selenium and iodine, and iodine and thyroid hormones in two groups of European women, control group and a group on medication with levothyroxine.

## Patients and method

This study was conducted as a pilot, cross-sectional and observational. Volunteers in the study were 24 European women, who were self-assigned into two groups, control group with healthy participants (n=13), and a group of women with Hashimoto's thyroiditis (HT) on medication with L-thyroxine (n=11). Both groups presented with

the moderate selenium deficiency. The plasma contents of selenium, TSH, T<sub>4</sub>, T<sub>3</sub>, creatinine, and e-GFR (Glomerular Filtration Rate) were determined. Any change in the participants' daily routine was not required. Plasma TSH, T<sub>3</sub>, and T<sub>4</sub> were measured using competitive immunoassays technique by the LabTests Laboratories in Auckland. Serum selenium was measured using inductively coupled plasma – dynamic reaction cell mass spectrometry by the Canterbury Health Laboratories in Christchurch, New Zealand. Urine samples were frozen and kept on -20°C until analysis. Urinary iodine concentration (UIC) was determined in spot samples by the new method called “Fast B” at the AUT University Laboratory [28]. Fast B method is improved Sandell-Kolthoff reaction, which is simple, rapid, inexpensive, and reliable, and flexible [29].

## Statistical analyses

All statistical analyses were conducted using SPSS for windows (version 22.0, SPSS Inc., Chicago, Illinois, USA). Variables in the study were normally distributed, although TSH had skewed distribution and was log transformed before statistical analyses. Descriptive statistics (mean  $\pm$  S.D, and frequencies) were presented for baseline characteristics, while Pearson product-moment correlation coefficient investigated the relationships between iodine and selenium, and iodine and thyroid hormones in both groups of participants. From UICs, estimated daily intake of iodine was calculated. Values with a p < 0.05 were taken as significant.

## Results

Women with Hashimoto's thyroiditis were older than women in the control group, 58.09  $\pm$  10.80 and 52.69  $\pm$  7.40 respectively. Both groups presented with the moderate selenium deficiency. The mean plasma selenium levels in the control group and the group of women with the Hashimoto's thyroiditis were 1.28  $\pm$  0.15, and 1.32  $\pm$  0.17 respectively. The mean urinary iodine level in the control group and the group of women with the Hashimoto's thyroiditis was 120.77  $\pm$  59.35 (median UIC was 128.00 µg/L), and 98.64  $\pm$  62.83 (median UIC was 95.00 µg/L), respectively. Estimated daily iodine intake of 150µg/day was achieved in five participants in the control group, and four participants in the group of women with Hashimoto's thyroiditis. Estimated median iodine intake in the control group and Hashimoto's group was 142.22 and 105.55, respectively. Pearson correlation analyses have shown no significant relationships between iodine and selenium, and iodine and thyroid hormones TSH, T<sub>4</sub>, and T<sub>3</sub> in both groups. The mean plasma levels of creatinine and eGFR were within optimal ranges in both groups.

## Discussion

This study is based on self-reported presence or absence of thyroid disease. Participants in the study were European women (n=24) who were self-assigned into the healthy control group (n=13) and a group of women with Hashimoto's autoimmune thyroiditis on medication with Levothyroxine (n=11). Both groups presented with the moderate selenium deficiency [30]. It has been suggested that maximal activity of selenoenzyme is reached at blood selenium levels above 1.27 µmol/L, or according to the recent research by Rayman plasma selenium levels in the range of 1.6 to 1.9 µmol/L are considered optimal for thyroid and overall good health [31]. Also the study by Karunasinghe *et al.* (2012) have suggested that the basic selenium requirement may vary with genotype for a number of variations in selenoprotein genes, suggesting that an effective dietary selenium intake for one person may be different from that for others. In the absence of this information,

recommended plasma selenium levels should be in the range of 1.27 – 1.90µmol/L [32].

Plasma levels of TSH and T4 are higher in the group of women with Hashimoto's thyroiditis ( $2.92 \pm 2.83$ ;  $14.27 \pm 2.45$ ) than in the control group ( $14.62 \pm 1.45$ ) respectively. On the basis of these measurements, it is difficult to draw any conclusion about the iodine nutritional status of women in both groups, because TSH and T4 are not proper markers of urinary iodine concentrations (UIC) in this study sample [14]. However, currently, the most practical marker of community iodine nutrition is the median UIC in casual samples (µg/L), since about 90% of iodine is excreted in urine, which represents an indicator of the adequacy of the iodine intake of that population. According to the International Council for Control of Iodine Deficiency Disorders, the World Health Organisation, UNICEF, and the Food and Nutrition Board of the U.S. National Academy of Sciences, the minimal UIC for iodine sufficiency was set up at 100 µg/L, which corresponds to a daily intake of 150 µg of iodine [33]. Following these recommendations, after mandatory fortification of bread with iodised salt in 2009, women in the control group had a moderate sufficiency of iodine with the median UIC of 128.00µg/day, while women in the Hashimoto's group had mild iodine deficiency with the median UIC of 95.00µg/day. These figures suggest that the iodine status of New Zealand adults in this study sample is now likely to be adequate for the healthy population (Table 3 and 4). The UICs below 50<sup>th</sup> percentile significantly differed between the two groups. Below the 20<sup>th</sup> percentile, women in Hashimoto's group had severe iodine deficiency with UIC of 14 µg/L, while women in the control group presented with the mild iodine deficiency of 63.80 µg/L (Table 2). Estimated median iodine intake in the control group and the group of women with Hashimoto's thyroiditis based on urine was 142.22 µg/day and 105.55 µg/day respectively, below RDI of 150 µg/day in both groups; although, lower in the Hashimoto's group (Table 1). The presence of iodine and selenium deficiencies in this study is supported by the study of Brough, *et al* (2017) with mild ID and low selenium intake of postmenopausal women in New Zealand [34]. Median UIC was 57 µg/L, while estimated median iodine intake based on urine was 138 µg/day, below RDI (150 µg/day). Another study by Edmonds *et al.* (2016) notified an improvement in iodine status from a median UIC of 53 µg/L reported in the 2008/2009 New Zealand Adult Nutrition Survey to 73µg/L in the study, which was far below the recommended range by WHO/UNICEF/ICCIDD, although median urinary iodine excretion (UIE) of 127 µg/day suggested that overall iodine status was likely to be adequate after mandatory fortification of bread in 2009[35].

Continuous changes in the iodine supply to New Zealand population through the time, showed that iodine is already established factor in the onset of thyroid autoimmunity (TAI) [36]. In susceptible individuals, iodine overload causes a paradoxical block of the organification of iodide (the so-called Wolff-Chaikoff effect), and of the iodine intra-thyroidocyte transport by the sodium-iodide symporter (NIS). It was shown that iodide-induced hypothyroidism was precipitated by either prolonged excessive intracellular iodide concentration, or transition from iodine deficiency to iodine sufficiency or excess, that increased the incidence of autoimmune thyroiditis (AIT) and hypothyroidism, especially in young women [37]. Autoimmune disease affects thyroid gland more than any other organ in the body [38,39]. Hashimoto's thyroiditis (HT) is a primary and permanent hypothyroidism, and the most common autoimmune disease. Chronic inflammation of the thyroid endocrine tissue is the major characteristic of the autoimmune process.

In our study, women with Hashimoto's thyroiditis on medication with Levothyroxine, besides moderate selenium deficiency are now categorized as a group of women with ID which is less pronounced in the group of women without thyroid disorder. In our study, no association was found between selenium and iodine, and thyroid hormones (Table 5). However, several studies indicated that effects of selenium deficiency or excess on thyroid hormone biosynthesis in severe ID were more likely to be more pronounced than in mild ID [40-43]. Although, according to Rasmussen *et al.* (2011), optimal selenium status might help to prevent iodine deficiency disorders (IDD), particularly thyroid gland enlargement. The study by Shukri *et al.* (2014), suggested that severe selenium deficiency may exacerbate ID. However, the results from our study are in line with results from the larger study carried out in New Zealand [44]. The authors suggested that there was no association between plasma selenium and thyroid hormones, and selenium deficiency did not significantly affect study population with marginal iodine status. These findings might be applicable only to the healthy control group in the current study.

## Conclusions

The results of the current study, with a relatively small sample size, are in line with the results from larger studies carried out in New Zealand. Iodine intakes appear to have improved after the mandatory fortification of bread with iodised salt in 2009, although ID is still a problem in New Zealand. Using an iodine fortified bread clearly made an impact on the overall iodine intake but not to the expected

level. Besides moderate selenium deficiency, at least half of the study participants had severe or mild ID in both groups. Considering the age of our study participants, women with Hashimoto's autoimmune thyroiditis, we might assume that they experienced iodine sufficiency or excess, or iodine insufficiency which could trigger autoimmune thyroid disease. Iodine is already recognized as established factor in the onset of thyroid autoimmunity. Also, in the study there was no association found between iodine and selenium, and iodine and thyroid hormones.

Any possible interaction between selenium and iodine is still unclear. It is necessary to have adequate monitoring of urinary iodine levels on a population level in order to detect further trends. It is essential to ensure New Zealanders are achieving adequate iodine intake.

### Acknowledgments

I would like to thank you Mark Duxbury who determined urinary iodine concentration (UIC) in spot urine samples by the new method called "Fast B" at the AUT University Laboratory. Also, I am very thankful for the financial support I received from the School of Interprofessional Health Studies, and help from my colleagues in the recruitment of participants. All participants in the study read the Participants Information Sheet and gave Written Consent. The Auckland University of Technology Ethics Committee (AUTC) No. 13/17, according to the Declaration of Helsinki, approved the study protocol.
